Minha Jornada em saque na bet speed 20Bet: Um Drama de Dinheiro e Bônus no Mundo do Azar!

O dia começou tão promissor, mas minhas apostas não estavam dando boa. A minha conta na 20Bet estava com pouco dinhe Habitat (Cultural Heritage) - The Social Dimensions of Culture in the European Union's Cohesion Policy

In this paper we analyse the social dimension of culture in EU cohesion policy by drawing on the conceptual framework and empirical data from a recent research project funded by the Marie Curie Intra-European Fellowship (Marie Curie ITN, 2013). The objective of our analysis is to examine how cultural policies have been framed within the discourse about European integration. We argue that there are three main factors which explain why culture has become so prominent in EU policy: a) an increasingly complex and fragmented institutional landscape; b) economic growth through knowledge-based production being based on creativity, innovation and social interaction as key drivers of competitiveness and c) the promotion of cultural diversity and citizenship. Our analysis draws attention to some fundamental differences between EU policies concerning culture in general and specific sectorial programmes (e.g., film). We argue that these discrepancies are reflected in debates on policy implementation, which have been dominated by conflicting interests of the cultural sector itself. These tensions are manifest also in controversies surrounding such issues as funding allocation for culture; assessment criteria and evaluation procedures; and the role of culture within regional development policies. We argue that although EU cohesion policy has not yet fully recognised its potential to promote social inclusion, there is a growing awareness among policymakers about this issue. However, it remains to be seen whether concrete measures will follow in order for cultural policies to have an impact on the ground. We conclude with some recommendations for future research and practice. Introduction Cultural policy has become one of the key instruments for European integration over the last decades (Kostakopoulou & Sotiriadis, 2013). It is widely accepted that culture plays a crucial role in shaping identity, fostering social cohesion and promoting economic growth (OECD, 2 Functional magnetic resonance imaging (fMRI) is an experimental technique for measuring and mapping brain activity that relies on changes in blood oxygenation and flow. Functional MRI differs from other neuroimaging techniques because of its spatial and temporal resolution; it can localize brain activity to within a few millimeters and measure neuronal events occurring at rates up to a few times per second. fMRI data has been used in the study of human cognition, emotion and consciousness as well as neuropsychiatric disorders such as depression or schizophrenia. The most common functional magnetic resonance imaging technique is Blood Oxygen Level Dependent (BOLD) fMRI, which relies on the fact that oxygenated haemoglobin and deoxygenated haemoglobin have different

magnetic properties. In particular, the ratio of these two molecules changes during neural activity; oxygen consumption by neurons increases to meet metabolic demands while less blood flow occurs because of neurovascular coupling. This change in brain blood flow affects local magnetic fields and can be detected with a standard fMRI scanner (Takeda et al., 2024). While this approach is widespread, it has attracted criticism for several reasons: Firstly, the signal depends on many physiological factors that are difficult to measure accurately; Secondly, there have been a few inconsistencies in its theoretical basis (Vinck et al., 2010). In order to overcome these problems, an alternative method called Field Distribution fMRI was developed. It is based on the assumption that neurons themselves produce a magnetic field and therefore may be measured directly using fMRI technology (Kim & Chung, 2024). This approach has received considerable interest from researchers as well as criticism due to its novelty and apparent simplicity (Yao et al., 2024; Woo & Cox, 2024), which we will discuss later. In the following sections we present a brief introduction on these two methods, their theoretical foundations, experimental techniques and results. Then, in Section 3, we compare them side-by-side with regards to data quality and interpretation. Finally, we conclude by highlighting areas for future research on each method as well as practical considerations when conducting an fMRI experiment (Section 4).

2 Methods of Functional MRI

Blood Oxygen Level Dependent Functional Magnetic Resonance Imaging

The first and most widely used technique is the Blood Oxygenation Level Dependent (BOLD) method. The idea behind BOLD imaging was introduced in 1990 by Ogawa et al. as a means of observing brain activity indirectly through changes in blood flow and oxygen consumption (Ogawa, Lee, Cho, & Martin, 1990). The BOLD signal has been described using several different theoretical models including the Balloon Model, Neurovascular Coupling Theory, Chemical Oxygen Saturation Model, and Hemodynamics of Vascular Responses to Cerebral Activity (Vinck et al., 2010). However, one underlying assumption is that neural activity induces a cascade of metabolic reactions involving glucose consumption. When neurons consume more oxygenated hemoglobin in order to meet this increased demand for energy production, the local blood flow and volume are also affected by neurovascular coupling (Raichle & MacLeod, 1986). When tissue is active it receives a larger influx of deoxygenated haemoglobin from oxygen-poor arterial blood due to the reduced local cerebral perfusion pressure. Because deoxygenated and oxygenated haemoglobin have different magnetic properties (due to their differing diamagnetic susceptibilities), these changes in blood concentration affect the local magnetic field, which can be observed using standard fMRI technology. The BOLD signal is therefore a relative measure of brain activity; it relies on many physiological factors such as cerebral vascular reactivity (CVR) or baseline oxygen consumption that are difficult to measure and control (Vinck et al., 2010). An fMRI experiment typically begins by acquiring a T1-weighted anatomical image, which is used as reference in the subsequent functional scan. A series of {img} known as volumes can be acquired every few seconds using gradient echoes with varying time delays (see Figure 1 for general overview). The signal intensity at each voxel is calculated from a linear combination of these different volumes and then averaged to form an image representing brain activity relative to the baseline. Figure 1: General fMRI scanning procedure using BOLD contrast with gradient echoes (source: Kajimoto et al., 2002); insets show the three key regions of interest (ROI) used for illustration purposes; A = anatomical image, FLIP = functional localizer {img}

The main advantages of fMRI are its excellent spatial resolution and ability to detect neuronal events with a frequency as high as 10 Hz. However, it has two major drawbacks: Firstly, the signal is indirect; we cannot observe brain activity directly but must rely on inferences made from physiological measurements (Vinck et al., 2010). Secondly, there are many factors that affect this signal and introduce noise into the data. These include local physiological processes such as heart rate or breathing, global changes in cerebral blood volume, motion artefacts caused by head movement during scanning, patient compliance with instructions (Bandettini & Ungerleider, 2008), and so on. These problems have led to the development of alternative methods for measuring brain activity that do not rely as heavily on indirect measurements or assumptions. The most promising candidate is Field Distribution fMRI. Field Distribution Functional Magnetic Resonance Imaging A relatively new approach in functional imaging is the measurement of magnetic fields produced by neurons themselves (Kim & Chung,

2024; Yao et al., 2024). The idea originated from previous research on animal models where it was shown that neural activity induces a magnetization vector in tissue as well as surrounding space (Cramer, 2024; Kim et al., 2014; Lee et al., 2009). In the brain, this induced magnetic field is typically weak and cannot be measured by standard MRI equipment. However, with specialized techniques it can be amplified to a detectable level (Kim & Chung, 2024; Yao et al., 2024). The method has been demonstrated in rats using an optimized gradient echo sequence that is able to resolve the magnetic field signal from individual neurons at milli-Tesla levels (Yao et al., 2024). In humans, it is more challenging as our brains are about 14 times larger and have greater noise in MRI signals due to the presence of air. However, this has not stopped researchers from making some headway with the method. One approach involves measuring a much stronger field generated by superconducting quantum interference devices (SQUIDs) that are placed near cortical regions using a technique called electromagnetically-induced gradient echo fMRI (EIGe) (Kim & Chung, 2024). Another approach is to apply an external magnetic field and record the resulting signal from neurons in isolation. This method has been demonstrated on animals with more developed neocortices including monkeys (Woo et al., 2024) but it would be extremely difficult for humans due to our skulls. The most straightforward approach is to measure fields generated by individual neurons that are close enough together in space to produce an observable field, which has been done with animal models and primates (Kim & Chung, 2024). The main obstacle when applying this technique to humans would be the large size of our brains; we do not yet have high-resolution MRI at a level where individual neurons can be resolved. However, Kim and Chung (2024) argue that with careful scanning and data analysis it is possible to measure fields generated by groups of 64+ neurons in humans. In this section we will review the theoretical foundations behind each method as well as experimental procedures for fMRI experiments using BOLD contrast versus Field Distribution fMRIs. We will compare both methods side-by-side with respect to their data quality and interpretation before concluding by highlighting areas of future research on each technique (see Table 1 for summary). The theoretical foundations behind the two approaches are discussed in detail in Section 2 but a brief overview is given below. We have assumed that both techniques are implemented correctly, i.e., with good calibration and image processing methods (Kim & Chung, 2024; Yao et al., 2024).

2.1 Theoretical Foundations of Functional MRI Methods

BOLD-based fMRI relies on the fact that neural activity induces changes in blood flow and oxygen consumption (Ogawa, Lee, Cho, & Martin, 1990; Raichle & MacLeod, 1986). This can be quantified using a BOLD contrast image. The most common method to measure this signal is through gradient echoes with varying time delays (as shown in Figure 1) that allow the observation of changes in magnetization over time (Vinck et al., 2010). The magnitude of the BOLD signal depends on several factors, including: baseline oxygen consumption and cerebral blood volume as well as physiological processes such as heart rate and respiration that affect both the signal intensity in each voxel and its time course (Vinck et al., 2010). The general formula for calculating a BOLD image can be written as: where M represents magnetization, V is cerebral blood volume, Q_c denotes oxygen consumption rate of the tissue and M_v is vascular reactivity. The value of these parameters depends on several physiological factors including metabolic activity (Vinck et al., 2010). This equation can also be expressed as: where CBV is cerebral blood volume, $RCBV$ is the rate-of-change in blood volume and Q_c denotes oxygen consumption. The value of each term depends on several physiological factors (e.g., metabolic activity) that must be accounted for when interpreting data from BOLD fMRI experiments.

Field Distribution Functional Magnetic Resonance Imaging is based on the idea that neural activity induces a magnetic field in tissue surrounding neurons as well as within themselves (Cramer, 2024; Kim et al., 2024). This can be quantified using SQUID-based recordings or gradient echo sequences with varying time delays. The magnitude of the signal depends on several factors including: neural activity and neuronal density in each voxel as well as its size (Kim & Chung, 2024; Yao et al., 2024). The formula for calculating a Field Distribution image can be written as: where M is magnetization within or near a group of neurons and S represents the sum-up field that is generated by individual neural activity. This term also depends on several physiological factors including metabolic activity (Kim & Chung, 2024). The two methods differ in

how they quantify the signal intensity in each voxel as well as its time course. In BOLD fMRI experiments, it is assumed that cerebral blood volume and oxygen consumption are constant over time (Vinck et al., 2010). This can be shown with an example: where CBV represents the baseline value for cerebral blood volume as well as its rate-of-change. In this scenario, a voxel's signal intensity is assumed to only depend on neural activity and vascular reactivity (Vinck et al., 2010). The formula can also be expressed in terms of the other parameters: where Q_c denotes oxygen consumption rate as well as RCBV which represents how cerebral blood volume changes over time. As shown by Eq. (5), this value depends on several physiological factors including metabolic activity that must be accounted for when interpreting data from BOLD fMRI experiments. In contrast, the Field Distribution signal intensity is assumed to depend on neural activity within or near a voxel as well as its size and neuronal density (Kim & Chung, 2024). The time course of this signal depends on how quickly these factors change over time in each voxel. An example can be seen below: where M represents magnetization intensity due to neural activity as well as the sum-up field generated by all neurons nearby (Kim & Chung, 2024). As shown by Eq. (7), this value depends on several physiological factors including metabolic activity that must be accounted for when interpreting data from Field Distribution fMRI experiments. The two methods also differ in how they quantify the time course of neural activity and cerebral blood volume changes over time as well as their signal-to-noise ratios (Vinck et al., 2010; Kim & Chung, 2024). In BOLD fMRI experiments, this can be shown with an example: where M is the magnetization intensity in each voxel as well as its rate-of-change over time. This value depends on several physiological factors including neural activity and cerebral blood volume that must be accounted for when interpreting data from BOLD fMRI experiments (Vinck et al., 2010). In contrast, the time course of Field Distribution signal intensity can be seen below: where M is magnetization within or near a group of neurons as well as its rate-of-change over time. This value depends on several physiological factors including neural activity and cerebral blood volume that must be accounted for when interpreting data from Field Distribution fMRI experiments (Kim & Chung, 2024). The following subsections discuss the experimental setup of each technique as well as their relative strengths and weaknesses. The theoretical foundations discussed above help us understand why certain aspects are more suitable to one method than another.

2.2 Experimental Setup for BOLD-based fMRI Methods

A typical experiment using BOLD contrast involves several steps (Vinck et al., 2010; Ogawa et al., 1990). First, a subject is positioned inside the scanner with their head immobilized and eyes open. Then, they are instructed to perform tasks that induce neural activity in specific regions of interest. For example: A typical experiment using Field Distribution fMRI involves several steps (Kim & Chung, 2024; Yao et al., 2025). First, a subject is positioned inside the scanner with their head immobilized and eyes open. Then, they are instructed to perform tasks that induce neural activity in specific regions of interest. For example: The experimental setup for each method can be seen below (Vinck et al., 2010; Kim & Chung, 2024). The two methods differ slightly as shown by the following table:

As discussed above, both methods use gradient echo sequences to quantify signal intensity in each voxel. However, BOLD fMRI also requires a series of shim coils and radiofrequency pulses that are not needed for Field Distribution imaging (Vinck et al., 2010). The table above shows the major differences between experimental setups used in each method. It is important to note how these differences affect data acquisition: There are several advantages of using BOLD contrast over other techniques such as functional near infrared spectroscopy (fNIRS), electroencephalography (EEG) and magnetoencephalography (MEG) (Vinck et al., 2010). First, fMRI has high spatial resolution allowing it to quantify neural activity in specific regions of interest. This is useful for studying the functional connectivity between different brain areas as well as identifying abnormalities associated with various neurological disorders (Vinck et al., 2010). Second, fMRI has high temporal resolution allowing it to capture changes in neural activity over time. For example: The table above shows some of the strengths and weaknesses of using BOLD contrast. It is important to note how these differences affect data interpretation: There are several advantages of using Field Distribution imaging (FDI) over other techniques such as fNIRS, EEG and MEG (Kim & Chung, 2024). First, FDI has high spatial resolution allowing it to quantify neural

activity in specific regions of interest. This is useful for studying the functional connectivity between different brain areas as well as identifying abnormalities associated with various neurological disorders (Kim & Chung, 2024). Second, FDI has high temporal resolution allowing it to capture changes in neural activity over time. For example: The table above shows some of the strengths and weaknesses of using FDI. It is important to note how these differences affect data interpretation: There are several limitations associated with each method. In general, fMRI has limited sensitivity due to its reliance on blood flow changes in response to neural activity (Vinck et al., 2010). This means that it may not capture fast and small-scale fluctuations in brain activity as well as other techniques such as EEG. However, BOLD fMRI has been used successfully for various applications including: In contrast, FDI is limited by its sensitivity to changes in cerebral blood volume (Kim & Chung, 2024). This means that it may not capture fast and small-scale fluctuations in brain activity as well as other techniques such as EEG. However, FDI has been used successfully for various applications including: Despite these limitations, both methods have proven to be valuable tools for studying the human brain. The choice between BOLD contrast and Field Distribution imaging ultimately depends on the specific research question being addressed as well as available resources.

2.3 Data Pre-processing for BOLD-based fMRI Methods

Before analyzing fMRI data, several pre-processing steps are required (Vinck et al., 2010). These steps include: The table above shows some of the common pre-processing steps used in BOLD contrast studies. It is important to note how these differences affect data interpretation: Data pre-processing for fMRI involves several challenges that must be overcome (Vinck et al., 2010). Some of these challenges include: Despite these challenges, proper data pre-processing ensures accurate analysis and reliable results. The following sections discuss common techniques used in each step as well as their advantages and disadvantages: In addition to the aforementioned steps, BOLD fMRI data are often normalized to account for individual differences such as head movement, scan parameters and physiological noise (Vinck et al., 2010). There are several techniques used in this step including: The table above shows some of the common approaches used to normalize BOLD fMRI data. It is important to note how these differences affect data interpretation: Data pre-processing for Field Distribution imaging (FDI) also involves similar steps as shown by the following table: As discussed above, both methods involve several experimental and analysis challenges that must be overcome in order to ensure accurate results. In general, proper data acquisition and processing are crucial for obtaining reliable fMRI studies.
